Keep the Kids Inside?

Juvenile Curfews and Urban Gun Violence

Jillian B. Carr[*] and Jennifer L. Doleac[†]

Date of current draft: June 2017

Abstract

Gun violence is an important problem across the United States. However, the impact of government policies on gunfire has been difficult to test due to limited and low-quality data. This paper uses new, more accurate data on gunfire (generated by ShotSpotter audio sensors) to measure the effects of juvenile curfews in Washington, DC. Using variation in the hours of the DC curfew, we find that this policy increases gunfire incidents by 150% during marginal hours. In contrast, voluntarily-reported crime measures (such as 911 calls) suggest that the curfew decreases gun violence, likely because of confounding effects on reporting rates.

1 Introduction

Gun violence is a chronic problem in the United States. Nationally in 2012, 11,622 people were killed by assault with a firearm.[1] Many more people are injured by guns each year: in 2011, 693,000 individuals were treated in emergency rooms for injuries due to assaults by firearms and similar mechanisms.[2] Gun violence takes a particularly large toll on young people: according to the CDC, homicide accounts for 18% of deaths for males ages 15-24, more than for any other age group. For black males, homicide is the leading cause of death in that age group, accounting for roughly half of all deaths (CDC, 2013).

Cohen and Ludwig (2003) wrote that "policymakers who are concerned about America's problem with lethal violence must ask: how can we prevent young men from shooting one another?" This has been a difficult question to answer, and continues to attract a great deal of academic and policy attention.[3] A primary challenge in studying gun violence is the selective underreporting of gunfire incidents. In this paper, we discuss the shortcomings of traditional, voluntarily-reported crime measures, and demonstrate the value of new data generated by audio sensor technology. As a case study, we use both types of data to measure the effect of juvenile curfew policies on urban gunfire.

Juvenile curfews are a popular but controversial policy used by cities across the country. They require young people to be home during the nighttime hours when crime is most prevalent. Their goal is to reduce criminal activity by keeping would-be offenders indoors, but these curfews might unintentionally reduce a deterrent effect that comes from having lots of people out on the streets. By incentivizing young people (and by extension their caregivers) to be at home, juvenile curfews remove potential bystanders and witnesses from public areas. Removing those people decreases the probability that any remaining offenders will get caught (because there are fewer witnesses who would call or assist the police), as well as the potential punishment (which would be higher if bystanders were injured). As Jane Jacobs wrote in 1961, "A well-used street is apt to be a safe street. A deserted street is apt to be unsafe." In addition, curfews change how police allocate their time. If curfew enforcement distracts police from more productive law enforcement activities, this too could reduce the deterrent effect. However, the net effect of juvenile curfews on public safety is unknown, and so the passage and enforcement of such policies continues unabated.

We use changes in curfew times in Washington, DC, to test the net effect of juvenile curfews on the number of gunfire incidents during marginal hours. DC's curfew time for anyone under age 17 is 11pm on

[2] CDC: National Hospital Ambulatory Medical Care Survey: 2011 Emergency Department Summary Tables.

[3] Much of the literature on gun violence has focused on the effects of laws that restrict gun ownership or use (e.g., Cook, 1983; Lott and Mustard, 1997; Black and Nagin, 1998; Ludwig, 1998; Duggan, 2001; Marvell, 2001; Moody, 2001; Ayres and Donohue, 2003; Donohue, 2004; Mocan and Tekin, 2006; Duggan, Hjalmarsson, and Jacob, 2011; Cheng and Hoekstra, 2013; Manski and Pepper, 2015). Overall, there is mixed evidence that these laws improve public safety; results depend heavily on identification strategy and the data used.

weeknights and midnight on weekends from September through June, and midnight on all nights during July and August.[4] In other words, the weekday curfew time changes from midnight to 11pm on September 1st, and back to midnight on July 1st, roughly following the school year. (We focus here on the September change because of concerns about data quality around the July 4th holiday.[5]) With a nod to the concept of a witching hour,[6] we will henceforth refer to the treated hour – 11-11:59pm on weekdays – as the "switching hour."

If curfews reduce crime, then when the curfew shifts to 11pm rather than midnight, crime during the switching hour should go down. To identify the effect of the juvenile curfew, we use a triple-differences strategy to compare the change in the 11pm hour on weekdays to changes during two sets of control hours: the 11pm hour on weekends (which is always before curfew), and the midnight hour (which is always after curfew). Controlling for gunfire during these hours should isolate the effect of the curfew change from the effects of unrelated seasonal changes in gun violence.

We use the full universe of gunfire incidents detected by an audio sensor technology called ShotSpotter (described in more detail below) as our outcome measure. The main advantage of using ShotSpotter data in this context is that their accuracy is unaffected by the change in curfew time, so we avoid the potential confounding effect of a simultaneous change in reporting. We show that this confounding effect is important in this context.

Using ShotSpotter data, we estimate that the juvenile curfew in Washington, DC, *increases* the number of gunfire incidents. Figure 1 plots mean residuals from our main specification, which controls for a variety of time and spatial characteristics as well as gunfire during the control hours described above (11pm on weekends and midnight on weekdays). There appears to be an increase in gunfire after September 1st. Figure 2 is an event-study-style graph that plots the coefficients for our main specification for each day. It shows no change in the estimated effect before September 1st (which supports the identifying assumption that the treated and control hours exhibit parallel trends, as discussed in greater detail below), and an increase in the coefficients after the curfew switches to 11pm on September 1st. In our regression analysis, we estimate that the juvenile curfew causes 0.045 more gunfire incidents per Police Service Area (equivalent

---

[4]The Juvenile Curfew Act of 1995 states that individuals under age 17 cannot be "in a public place or on the premises of any establishment within the District of Columbia during curfew hours." Exceptions are made for several reasons, including if the juvenile is accompanied by a parent or guardian, is working, or is involved in an emergency. During most of the year, curfew hours are 11:00pm on Sunday, Monday, Tuesday, Wednesday and Thursday nights, until 6:00am the following morning. They are 12:01am until 6:00am on Saturday and Sunday (that is, Friday and Saturday nights). During July and August, curfew hours are 12:01am to 6:00am every night. Juveniles who are caught violating curfew are taken to the nearest police station and released to the custody of their parents. They can also be sentenced to perform community service. Parents who violate the curfew law by allowing their child to be in public during curfew hours can be fined up to $500 per day. The curfew policy in Washington, DC, is very similar to policies in cities across the country.

[5]In particular, increased firecracker use leading up to July 4th means that a large number of detected gunshots might be firecrackers that sound like gunfire, providing little information about public safety. We discuss this concern in more detail below.

[6]"The witching hour... was a special moment in the middle of the night when every child and every grown-up was in a deep deep sleep, and all the dark things came out from hiding and had the world all to themselves." – Dahl (1982)

to a police precinct) during the switching hour after September 1st than would have occurred without the curfew; this is a 150% increase relative to the late-curfew baseline. With 31 Police Service Areas in our sample and 5 weekdays per week, this aggregates to seven additional gunfire incidents per week, city-wide, during the switching hour alone.

Using voluntarily-reported crime data — such as 911 calls or reported crimes — for this analysis would not allow us to study this effect. Like some other types of crime, gun violence is likely underreported in a highly-selected manner. Particularly in inner-city communities that distrust the police, gunshots may not be reported unless the bullet hits someone and medical assistance is required (and even then some individuals might avoid hospitals to avoid arrest, or might have someone drive them to the ER instead of calling 911 and drawing police to their neighborhood). Most policy interventions that aim to reduce gunfire probably also affect reporting rates. This makes it difficult to analyze policy effects on gunfire. Any empirical analysis based on traditional data – for instance, reported gunfire (via 911 calls) or gun-involved crime (via reported crime data) – will be biased, and often the direction of the bias will be unknown (Pepper, Petrie, and Sullivan, 2010).

In the past, these concerns have limited researchers to using homicide (which is reported with near-perfect accuracy) as an outcome measure. There are two problems with this: first, homicide is a relatively rare event that is becoming rarer as medical technology improves (saving more victims' lives), and this low incidence makes it difficult to detect policy effects. Second, homicide is not the only outcome of interest. Ideally, we would observe all instances where a gun threatened someone's safety. If we define gun violence in this way, a very small share of gun violence results in homicides.[7] ShotSpotter data from urban areas get closer to measuring all threatening uses of guns.

For comparison, we consider the effects of the curfew on reported crime and 911 calls, using geo-coded data from DC's Metropolitan Police Department (MPD). The results are imprecise but generally suggest that the early curfew *decreases* gun violence. For instance, we estimate that the juvenile curfew reduces the number of 911 calls to report gunfire by 22%. This different (and we argue incorrect) conclusion is likely due to the simultaneous effect of the curfew on reporting behavior, and highlights the problem with using voluntarily-reported crime data for the study of gun violence.

---

[7]In DC, only 0.5% of gunfire incidents result in a homicide (Carr and Doleac, 2016).

1.1 Background on juvenile curfews

In general, violence-prevention policies can work one of two ways: (1) by deterring violence,[8] or (2) by incapacitating would-be offenders.[9] If offenders have high discount rates and are unlikely to be deterred by future punishments — a la Becker (1968) — then limiting their opportunities to commit crime could be the most effective crime-prevention policy. With this in mind, cities across the United States have enacted and actively enforce juvenile curfews.

Juvenile curfews are common, but they are extremely controversial for several reasons: (1) They give police officers discretion to stop any young-looking person who is out in public at night. Some worry this results in disproportionate targeting of racial minorities and contributes to tense relationships with law enforcement.[10] (2) They override the decisions of parents who would allow their kids to stay out late. (3) They may encourage kids at risk of abuse to return home to unsafe environments. (4) They divert police resources from other, potentially more productive, activities.

There is little previous work on the causal impacts of juvenile curfew policies. Kline (2012) studied the impact of juvenile curfews on juvenile and non-juvenile arrest rates in cities across the country. He finds that juvenile arrests go down following the enactment of new curfew laws. He also finds evidence that arrest rates for older individuals decline, suggesting that juvenile curfews have spillover effects. However, arrest rates are a function of not only criminal behavior, but police behavior and witnesses' behavior. Curfew laws likely affect all of these. Of particular concern, arrest rates might fall if witnesses and victims are less willing to cooperate with police as a result of heavy-handed curfew enforcement. Similarly, enforcing the curfew could distract police from solving criminal cases. Both effects could contribute to the reduction in arrests found in the study. The advantage of looking at arrest rates is that the age of the offender is known; the advantage of using ShotSpotter data is that we are able to isolate effects on actual criminal activity.

Another key difference between our paper and Kline (2012) is that our empirical strategies address slightly different, but highly complementary, questions: Kline considers the net effects of implementing new curfew policies, including any distrust they might generate. In contrast, we consider the effect of incentivizing local residents to go home during a marginal hour in a city with an existing curfew. This allows us to focus on

---

[8]Deterring crime requires changing the relative costs and benefits of committing a crime in such a way that would-be offenders rationally choose not to offend. Deterrence-based policies typically involve increasing the punishment or the probability of getting caught.

[9]Incapacitation is often thought of as synonymous with incarceration. In this paper, we follow the literature and refer to policies that operate by changing the relative costs and benefits of being in a particular location at a particular time as "incapacitation polices." The idea is that these policies reduce the *opportunity* to commit a crime, rather than the relative costs and benefits of committing a crime, per se. Mandatory schooling and summer jobs for teens are examples of policies that operate in this manner.

[10]A recent interview with several DC teenagers provides anecdotal evidence that this is a legitimate concern in the city. An excerpt: "Benn: And do you feel you're being protected and served by the police? Doné: No way. I feel more threatened by them than by anybody else. Benn: Would you all ever help a police officer to apprehend a criminal? Doné: No. Martina: Hell no." (Politico, 2015)

the countervailing incapacitation and deterrent effects of curfews. However, our estimates do *not* capture these policies' effects on residents' trust of the police; such effects could worsen public safety further.

There is a slightly larger literature on other types of non-incarceration incapacitation policies. For instance, mandatory schooling keeps juveniles occupied when they might otherwise be unsupervised and likely to get into trouble. Anderson (2014) uses minimum dropout ages to measure the effect of mandatory school attendance on crime. He finds that minimum dropout age requirements decreased arrest rates for individuals aged 16 to 18 by 17%. Jacob and Lefgren (2003) also study the impact of school attendance on crime, using exogenous variation in teacher in-service days to estimate the causal impact of being in school on juvenile delinquency. They find that juvenile arrests for property crimes go down by 14% when school is in session, while juvenile arrests for violent crimes go up by 28%. This suggests that gathering juveniles in one place unintentionally increases interpersonal conflict that spills over into non-school hours.[11]

We view the present study as contributing to the academic literature in several ways: (1) It measures the public safety impacts of juvenile curfews, which are a controversial but widely-used crime-reduction policy about which there is little empirical evidence. (2) To our knowledge, this is the first study to use ShotSpotter data, or any data generated by high-tech surveillance tools, to evaluate policy effects. It shows that using more accurate crime data based on sensors, rather than human reporting, can lead to qualitatively different conclusions about policy effects. (3) It considers the net effects of non-incarceration incapacitation policies on criminal behavior, thereby adding to a growing literature on this topic. (4) It addresses gun violence, which is of particular interest in the United States but is generally very difficult to study due to the lack of reliable data.

The paper proceeds as follows: Section 2 describes the data; Section 3 describes our empirical strategies; Section 4 describes our results and compares the gunfire effects with effects on reported crime and 911 calls; and Section 5 discusses the results and concludes.

2   Data

2.1   ShotSpotter

ShotSpotter data have two key advantages over traditional reported crime data: (1) they have accurate and precise time and location stamps, and (2) they are not subject to selective underreporting that could bias empirical estimates. By using better data, we: improve the precision of estimates by reducing measurement error; remove the selection bias resulting from variation in reporting rates over time, populations, and

---

[11]Note that both of these studies again use arrest rates as outcome measures. Despite that measure's flaws, it is commonly used in crime studies because it includes information on offenders' ages.

geographic areas; and eliminate the confounding effects of policies' simultaneous influences on reporting and crime.

We use ShotSpotter data from Washington, DC, from January 2006 through June 2013, aggregated to the level of Police Service Areas (PSAs).[12] The technology was first implemented in Police District 7 (Anacostia) in January 2006, then expanded to Police Districts 5 and 6 in March 2008, and to Police District 3 in July 2008. These are the areas of DC that had the highest crime rates, and so were expected to have the highest rates of gunfire. We therefore interpret our results as informative about the impacts of juvenile curfews in high-crime urban areas. While shots are detected outside of these targeted areas, we restrict our attention to Police Districts 3, 5, 6, and 7, since the data from those areas are the most accurate.

ShotSpotter technology consists of audio sensors installed around the city; these sensors detect gunshots, then triangulate the precise location of the sound. A computer algorithm distinguishes the sound of gunfire from other loud noises, and human technicians verify those classifications.[13] Once verified, this information is relayed to law enforcement so that police officers can quickly respond to the scene.

There are some false positives or negatives in the data — that is, noises that aren't gunshots that are recorded as gunshots, or gunshots that are missed — but in general these mistakes will be randomly distributed, and unaffected by the policy intervention we're studying. (The best evidence suggests the false negative rate is very low — less than 1%. The false positive rate is much more difficult to estimate, since the purpose of the technology is to detect gunfire that is not reported by others. See Carr and Doleac, 2016, for a review of current evidence on ShotSpotter's accuracy.) However, the false positive rate will be higher when activity that sounds like gunfire is more likely – in particular, note the spikes in detected gunfire incidents around New Year's Eve and July 4th, presented in Figure A.1. These spikes undoubtedly include some celebratory gunfire, but also false positives from fireworks and firecrackers. Of particular concern for our analysis, the use of firecrackers might increase leading up to the July 4th holiday, as they tend to be more available in stores at that time of year. Figure A.2 shows that there is an increase in detected gunfire in the month before July 4th. If this is largely due to local residents setting off firecrackers, it does not tell us anything meaningful about public safety. Of even greater concern, if juvenile curfews reduce this activity by incentivizing some of those firecracker-users to go inside earlier, then it might appear that the curfew decreases gunfire when in fact it simply reduces firecracker use. (Alternatively, the curfew could increase firecracker use if this activity seems safer when streets are emptier.) This motivates us to exclude the July 1st curfew change from our main analysis, though we will show that our main estimate is similar if we include it.

---

[12]Each Police District is composed of seven or eight PSAs; there are 31 PSAs in our sample.

[13]The sounds are classified as gunshots, construction, fireworks, car backfire, and so on. Only those classified as gunshot incidents are included in our data.

Some readers might wonder if, by removing people from the streets, juvenile curfews reduce street noise, and if this improves the ability of the acoustic sensors to detect gunfire. We do not believe this is an issue here, for two reasons: (1) The sensors are intentionally placed throughout the targeted coverage area in a way that ensures they are in reasonably close proximity to any potential gunshot. Concerns about reduced data quality outside of this targeted area, where sensors would be farther away, are the main reason we focus exclusively on the ShotSpotter-targeted Police Districts. (2) The decibel level of gunfire (166-170 decibels) is far louder than that even at a rock concert (110-120 decibels).[14] (Decibels are measured on a logarithmic scale, so a 10-decibel increase signifies a 10-fold increase in the sound intensity.) A firm called Soundhawk measured street noise in several major U.S. cities, and its estimates ranged from 90 decibels on Willshire Boulevard in Los Angeles, to 98 decibels at the intersection of Market and Geary Streets in San Francisco, to 104 in Time Square in New York City[15] – all levels that would not drown out the sound of gunfire. Sounds that are farther away will be less powerful, but since gunfire and other street noise both occur on the street level, surrounded by ShotSpotter sensors, the effect of differences in relative distance will be negligible.[16] Given that the sound of gunfire is approximately 1 million times as powerful as street noise in Time Square (60 decibels difference = 10^6 times as powerful), we do not expect changes in street noise in DC to affect the rate at which ShotSpotter detects gunfire. However, ultimately there is no way for us to test this. We thus proceed on the assumption that juvenile curfews do not affect ShotSpotter's data quality.

One detail that is missing from ShotSpotter data (because there's no way for the sensors to detect it) is the context in which the gun was fired: Was it fired in anger, with the intent of harming someone? Was it fired recklessly, in a place where bystanders could be hurt? Or was it fired into a wall during target practice, or into the ground to test whether the gun worked? It would be helpful to be able to distinguish the first two circumstances from the last two, but unfortunately we cannot. In dense urban areas such as Washington, DC, discharging a weapon within city limits for any reason is illegal, because it is presumed likely that someone could get hurt. We will discuss the ShotSpotter data as if every gunshot detected in DC is dangerous, but acknowledge that some might not be. At the very least, every gunshot is a crime in this context.

ShotSpotter is currently active in over ninety cities in the United States; while considered proprietary in most locations, the data used in this paper are available from the MPD via public records request. The data include the date and time that the gunfire incident was detected, the latitude and longitude of the

---

[14]Decibel ratings are from the Center for Hearing and Communication: `http://chchearing.org/noise/common-environmental-noise-levels/`.

[15]For more information, see
`http://elevatingsound.com/noise-levels-of-urban-america-why-the-city-soundscape-needs-to-be-transformed/`

[16]As distance from the source, r, increases, sound intensity decreases by $1/r^2$. This means that doubling the distance from the source drops sound intensity by only about 6 decibels. See `http://www.sengpielaudio.com/calculator-squarelaw.htm` for more.

incident, and whether the incident consisted of a single gunshot or multiple gunshots. During the period of interest (July 30th through October 4th, for the years 2006-2012), there was an average of 7.8 gunfire incidents per day across the Police Districts where ShotSpotter was implemented. On average, 1.0 per day occurred during the 11pm hour. Table 1 presents summary statistics.

2.2 Reported crime and 911 calls

For comparison, we repeat the main analysis using data on reported crime and 911 calls from the MPD. Our goal is to see how our conclusions about the curfew's effect would differ if we used traditional crime measures that are sensitive to changes in reporting. We therefore construct outcome measures that, without ShotSpotter data, would be the best available to study gun violence.

We use geo-coded data on reported crime and 911 calls from 2011 and 2012, aggregated to the PSA-level.[17]

The reported crime data include reports of: homicide, sexual abuse, assault with a dangerous weapon, robbery, burglary, arson, motor vehicle theft, theft from an automobile, and other theft. We code the first four crime types as "violent crimes," and also consider homicide separately. The data include information on the weapon used, if any; we code any crime in which a gun is listed as the weapon as a "gun-involved crime." The time and location stamps will generally be less precise than in the ShotSpotter data.[18]

The 911 call data include all calls for service, not necessarily for the police. The outcome measures of interest in this dataset are: all calls, calls for police, and calls to report gunshots. As for the reported crime data, the geo-codes and time stamps will be less precise than in the ShotSpotter data.[19]

As above, we restrict our analysis to the areas covered by ShotSpotter (Police Districts 3, 5, 6, and 7). Summary statistics are in Table 1.

2.3 Other data

We use weather data (temperature and precipitation) from the National Oceanic and Atmospheric Administration (NOAA) as controls. Local data are available at the richest level (hourly and daily) based on measurements from the Reagan National Airport weather station, located just outside the city.

We also collect information on DC public school calendars directly from the school district, to control for school year start and end dates.

---

[17]Due to a technical problem at the MPD, geo-coded data on reported crime are not available for dates prior to January 2011. The MPD does not maintain 911 call data for more than three years, so these are also unavailable before January 2011.

[18]The geo-codes are reported at the block level. The times are often estimates based on victims' and witnesses' recollections, and/or the time the incident was reported.

[19]The geo-codes will often be the address where the caller is calling from, rather than the location of the crime (this will be particularly problematic for reported gunshots, where the shots could have been fired blocks away from where they were heard). The time stamp is when the call was received.

3   Empirical Strategy

We exploit the September 1st curfew change from midnight to 11pm as a natural experiment that allows a triple-differences analysis: Beginning on that date, the switching hour is treated by the curfew, but there is no curfew change in other hours.[20] The change in the curfew time roughly follows the academic year; school starts in late August in DC.[21] For this reason, we will need to be careful to isolate the effects of the curfew time from that of unrelated seasonal changes in activity.

We use two sets of control hours to do this. The first is the 11pm hour on weekends, and the second is the midnight hour. Both sets of control hours are subject to the same seasonal changes in activity but are not affected by the curfew change. Using a triple-differences (DDD) specification, we compare the difference in gunfire during the 11pm hour (which is treated) to gunfire during the midnight hour (which is a control), across weekdays (treated) and weekends (control), testing for a differential effect during the switching hour. If the juvenile curfew is driving any observed change in gunfire, the curfew time change should affect the 11pm hour on weekdays (the switching hour), netting out the effects on the control hours. (We will confirm below that the curfew does not shift crime to or from the midnight hour.) We estimate the following using Ordinary Least Squares:

$$Gunshots_{h,d,p} = \alpha + \beta_1 EarlyCurfew * Weekday * 11pmHour_h + \beta_2 Time_d +$$
$$\beta_3 Time * EarlyCurfew * Weekday * 11pmHour_h +$$
$$\delta_1 School_d + \omega_d + \lambda_{dayofweek} + \gamma_{year} + \rho_{PSA} + e_{d,p}, \tag{1}$$

also including all single and pairwise combinations of the *EarlyCurfew*, *Weekday*, and *11pmHour* terms, as well as those terms interacted with *Time*.[22] In the above specification, h is the hour of observation, d is the day of observation and p is the Police Service Area (PSA). *Early Curfew* is an indicator for whether the weekday curfew time is 11pm, instead of midnight (that is, whether the date is September 1st or later). Our baseline specification controls for a linear time trend based on the day of the year, and allows the slope to vary before and after the curfew change (represented in Equation 1 by the terms *Time* and *Time*EarlyCurfew*Weekday*11pmHour*); the estimates are similar if we instead control for quadratic or cubic functions of time (as discussed in Section 4). *School* indicates whether the school year is in session, and controls for any independent effect of school attendance on behavior. ω_d is a vector of weather variables,

---

[20]As discussed above, we do not use the July 1st curfew time change in our main analysis due to the confounding effect of changes in firecracker use around the July 4th holiday.

[21]School start dates vary from year to year, and do not perfectly coincide with the September 1st curfew change: August 28, 2006; August 27, 2007; August 25, 2008; August 24, 2009; August 23, 2010; August 22, 2011; and August 27, 2012.

[22]For a complete list of these control variables, see Table A.2.

including temperature and precipitation. $\lambda_{dayofweek}$, γ_{year}, and ρ_{PSA} are fixed effects for day of the week, year, and PSA, respectively. Standard errors are clustered by day of the year to account for serial correlation across hours and spatial correlation across PSAs. The primary coefficient of interest is β_1; this tells us if the early curfew time has an effect on the level of gunfire during the switching hour, relative to the control hours. The outcome measure, *Gunshots*, is the number of gunshot incidents detected by the ShotSpotter sensors.[23] The sample is 11pm–12:59am, on weekdays and weekend days.[24]

Recall that Figure 1 plots residuals for the DDD specification (excluding the treatment variable and other interactions with *EarlyCurfew*). Figures A.3 and A.4 break this DDD approach into its two component difference-in-difference comparisons. These figures, respectively, plot residuals for the difference in gunfire between 11pm on weekdays and 11pm on weekends, and between 11pm and midnight on weekdays. We see an increase in gunfire after September 1 when comparing 11pm on weekdays with the same hour on weekends. There appears to be a slight, upward change in trend after September 1 when comparing 11pm on weekdays with midnight on weekdays.

As mentioned in Section 2, we are concerned that data around the July 1 curfew change is heavily contaminated by false positives (firecrackers), and that that false positive rate might be affected by the curfew (if the curfew affects firecracker use). We therefore focus our main analysis on the September 1 change, but will also show the effect when both curfew changes are included.

Our identifying assumption in this analysis is that, absent the curfew change, the amount of gunfire during the switching hour would have evolved similarly to that in the control hours. (The control hours are not necessarily unaffected by seasonal changes; their purpose is to absorb any seasonal changes that would also affect the switching hour.) This is commonly referred to as the "parallel trends" assumption. Figure 2 supports this assumption: there is no apparent trend in gunfire during the switching hour, relative to the control hours, before September 1st. We check that the trends during treated and control hours appear similar during the pre-period in two additional ways: (1) Graphing pre-period gunfire during the treated and control hours, and (2) formally testing for differences in trends during the pre-period, by allowing the time trend to differ for treated and control hours and testing for whether any difference is statistically significant.

Figure A.5 shows residualized daily gunfire during the treated and control hours leading up to September 1st. The graphs are noisy, but during this pre-period the amount of gunfire during the switching hour appears to track that during the 11pm weekend hour particularly well. During the midnight hour, the trends

---

[23]We get very similar estimates if we use a Poisson model, and if we use a Logit model with a binary outcome measure of whether any gunshots were detected.

[24]Our sample includes days within 33 days of September 1st. In a previous version of this paper, we used a Regression Discontinuity design with an Imbens-Kalyanaraman optimal bandwidth of 33 days. We abandoned that empirical approach due to insufficient statistical power, but kept the 33-day cutoff to define the sample since we are unaware of a better way to define an optimal sample for a DDD analysis. Our estimates are very similar for a range of sample definitions from 5 to 50 days on either side of the curfew change; results available upon request.

do not track quite as closely, but still do not appear to diverge. More rigorously, Table A.1 shows there is no significant difference between the pre-period trends in the 11pm and midnight hours, or the 11pm weekday and 11pm weekend hours. Combined with Figure 2, this provides evidence that these control hours are good counterfactuals for the switching hour in the weeks leading up to the curfew time change, and supports the assumption that they would continue to be good counterfactuals after the curfew change. We therefore proceed with the DDD analyses when using the ShotSpotter data.

We also test the parallel trends assumption for the reported crime and 911 call data. Because both reporting and actual crime affect these traditional crime measures, our parallel trends assumptions may be less likely to hold now than before. We consider a formal test of whether pre-period trends differ for these new outcome measures, and Table A.3 shows the results: there is no significant difference between the weekday and weekend trends, but there is a marginally significant difference between the 11pm and midnight trends in reported crime. To be conservative, we will focus on difference-in-difference (DD) estimates using 11pm on weekends as control hours, for our comparison analyses.

4   Results

Table 2 presents the results of the ShotSpotter data analysis.

Column 1 shows our main result, which estimates the effect of the juvenile curfew on the number of gunfire incidents. We find that an earlier curfew increases the number of gunfire incidents by 0.045 during the switching hour, or 150% of the baseline. Note that while this estimate is statistically significant ($p < 0.05$) it is imprecise; the 95% confidence interval suggests gunfire incidents increase by 19–280% of the baseline – though even a 19% increase in gunfire is economically meaningful. Recall that observations are at the PSA-level, and our data cover 31 PSAs across the city. The estimated effect size of 0.045 implies seven additional gunfire incidents per week, during the switching hour alone.

The coefficients for the time trend (and interactions thereof) are omitted from Table 2; the full results of our DDD specification are in Table A.2. We do not find an effect of the curfew change on the trend in gunfire: the coefficient on *Time * Early Curfew * Weekday * 11pm Hour* is near-zero and statistically insignificant.

Column 2 of Table 2 estimates the DDD effect when both the July and September curfew changes are included.[25] The data from June and July add a great deal of noise, so the standard error is larger, but the coefficient suggests that the curfew increases gunfire by 0.037 incidents. This is very close to our main estimate of 0.045.

---

[25]We exclude July 1-7 as those days are extreme outliers due to holiday fireworks.

For robustness, we conduct the DDD analysis using different functional forms of the time trend. Recall that our preferred function is linear; we consider quadratic and cubic functions as well. Estimates, presented in Columns 3 and 4 of Table 2, are nearly identical to our preferred estimate in Column 1, though their statistical significance decreases as including more terms reduces statistical power.

Next, we test the effect of the curfew change on gunfire during the other hours of the day. If our effects are being driven by the change in the deterrent effect due to the curfew change, we should only see a statistically significant increase during the switching hour. That is what we find. Figure 3 graphs the estimates by hour. Using a DD specification with only weekend hours as controls (because the concern is that all hours are treated, we don't want to select another hour on weekdays as a control), we see that estimates are generally small and all are statistically insignificant, except for the positive estimate for the 11pm (switching) hour. However, there is evidence that part of that increase is due to shifting from other times.[26] The coefficient for 10pm is negative and about half the size[27] of our switching hour estimate; this suggests that some of the observed increase in gunfire is due to people delaying gunfire until after the curfew time.[28] This is consistent with the hypothesis that people respond to the relative deterrent effects across these hours caused by the decrease in potential witnesses and bystanders. We see no effect in the midnight hour, which we use as a control hour in our DDD analysis. (This is important, because if the curfew affected both hours – by shifting post-curfew gunfire from midnight to the switching hour – then midnight would not be a valid control and the DDD estimate would be biased upward.)

Finally, we estimate the effect of the curfew on reported crime and 911 calls, for comparison. Recall that we are now using a DD specification with 11pm on weekends as control hours. The results are presented in Table 3. Since we are using a shorter time period, we lose a great deal of statistical power, but the ShotSpotter data estimates are similar in magnitude to those presented above. The DD specification estimates that the earlier curfew increases gunfire incidents by 154% of the baseline (close to the respective 150% estimate using the longer time period). In contrast, the reported crime and 911 call data suggest that the earlier curfew *decreases* gun violence.

The results are less precise than before, and should be considered suggestive. However, it is striking that most of the coefficients are negative when using reported crime and 911 call data. Indeed, the outcomes most likely to be used to measure gun violence – gun-involved reported crimes and 911 calls to report gunfire – have negative coefficients. Using those traditional data sources would therefore lead to the opposite conclusion about the effectiveness of this policy. Our estimates suggest that the curfew reduces the number of gun-

---

[26]The net effect over the full day is an increase of 0.016 incidents; this aggregate effect is statistically insignificant, but indicates that not all of the increase during the switching hour was due to the shifting of gunfire from other hours.

[27]The coefficient for the 10pm hour is -0.025.

[28]The fact that not all gunfire is shifted from other hours is consistent with the finding in Doleac and Sanders (2015) that violent crime is not easily shifted across the day.

involved crimes by 107%, and the number of 911 calls to report gunfire by 22%. These qualitatively different results are likely due to confounding changes in reporting rates. In general, these comparison results could be biased upward or downward – the direction of the bias is unclear a priori. The typical solution to this problem, using homicide as an outcome measure, does not help here: there were only three homicides during the switching hour — far too few to produce a meaningful estimate.

5   Discussion

In this paper, we use new gunshot incident data from ShotSpotter to measure the effects of a city-wide juvenile curfew on gun violence. These data are not affected by the selective underreporting that plague traditional reported crime data. The resulting empirical estimates do not suffer from the biases that make empirical results throughout the literature difficult to interpret. This is crucial for determining the true impact of any policy on public safety.

The curfew policy in Washington, DC, was enacted in 1995 as an effort to improve public safety. Similar curfew laws are in effect across the United States, but are controversial, and in some cases have been ruled unconstitutional. While their goal is to improve public safety through an incapacitation effect, incentivizing local residents to go home and distracting cops from other duties could reduce a deterrent effect on street crime. The net effect of the policy is theoretically ambiguous. We show that in this city, the juvenile curfew law *increases* the number of gunfire incidents, by 0.045 additional incidents per PSA, during the switching hour. With 31 PSAs in our dataset, this aggregates up to 1.40 extra gunfire incidents per weekday, or 6.98 extra gunfire incidents per week, across Police Districts 3, 5, 6, and 7.

Our results suggest that curfew laws are not a cost-effective way to reduce gun violence – in fact, we find that curfews increase gun violence. This does not necessarily mean that juvenile curfews are not cost-effective more broadly. We cannot measure impacts on other types of crime, particularly minor offenses. It could be that curfews reduce those offenses enough to offset the increase in gun violence and the infringement on juveniles' rights and parents' choices. It is also possible that even if curfews do not reduce the number of gunshots, they might reduce the number of victims when there are fewer innocent bystanders in the area. Saving lives is, of course, a good thing. However, residents may not consider such an impact evidence of a real improvement in public safety, since the curfew makes it more dangerous to be outside. (Preventing victimization by telling people to hide in their homes is clearly a band-aid solution.) Finally, juvenile curfews might increase domestic violence by incentivizing at-risk kids (and their caregivers) to be home at night. This is an important potential cost that should be considered.

Empirical evidence on this topic is particularly necessary in light of broader concerns about how to

improve trust between law enforcement and city residents. Juvenile curfews are the type of policy that many worry worsens tensions between inner-city communities and the police. Ours is only the second rigorous examination of the effects of juvenile curfews on public safety. This is probably due in part to the difficulty of convincingly identifying impacts of a policy that could affect both criminal activity and reporting rates. Indeed, we show that we would get a qualitatively different result if we were using voluntarily-reported crime data, such as 911 calls to report gunfire. ShotSpotter data on gunfire incidents provide a unique opportunity to isolate the effect on crime from the effect on reporting.

6 Main tables and figures

Figure 1: Effect of the 11pm curfew on gunfire incidents: DDD residuals

Notes: Points show differences in mean residuals, by day, from a regression including all of the control variables from Equation 1 and a linear term controlling for the day of year. Analogous to a DDD estimator, we present the difference in mean gunshots during the 11 pm hour on weekdays and weekends minus the difference in mean gunshots during the midnight hour on weekdays and weekends. The weekday curfew changes from midnight to 11pm on September 1. Standard errors are clustered by day of year. Data source: Authors' calculations using ShotSpotter data from the Washington, DC, police department, 2006–2012. Geographic areas covered: Police Districts 3, 5, 6, 7; gunfire incidents are aggregated to the Police Service Area (PSA).

Figure 2: Effect of the 11pm curfew on gunfire incidents by day relative to the curfew change
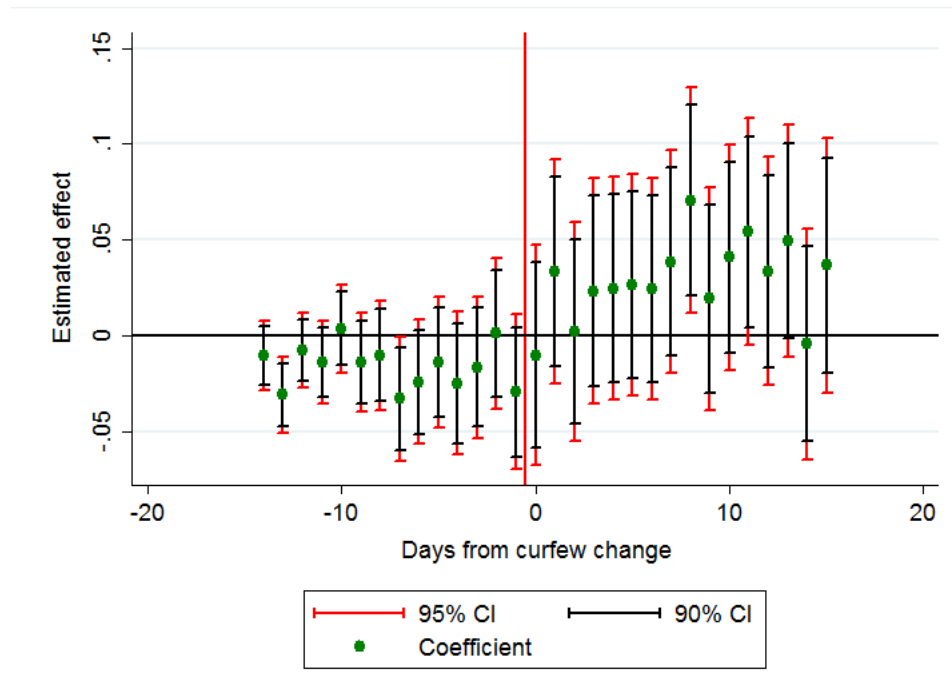

Notes: The figure plots treatment variable coefficients and their 90% and 95% confidence intervals, by day, from the DDD analysis of the effect on gunfire during 11pm on weekdays, relative to two sets of control hours: 11pm on weekends, and midnight. Day 0 is September 1st, when the weekday curfew changes from midnight to 11pm. Standard errors are clustered by day of year. Data source: Authors' calculations using ShotSpotter data from the Washington, DC, police department. Sample: 11pm–12:59am on July 30 through October 4, for the years 2006–2012. Geographic areas covered: Police Districts 3, 5, 6, 7; gunfire incidents are aggregated to the hour and Police Service Area (PSA) levels.

Figure 3: Effect of the 11pm curfew on gunfire incidents by hour of day
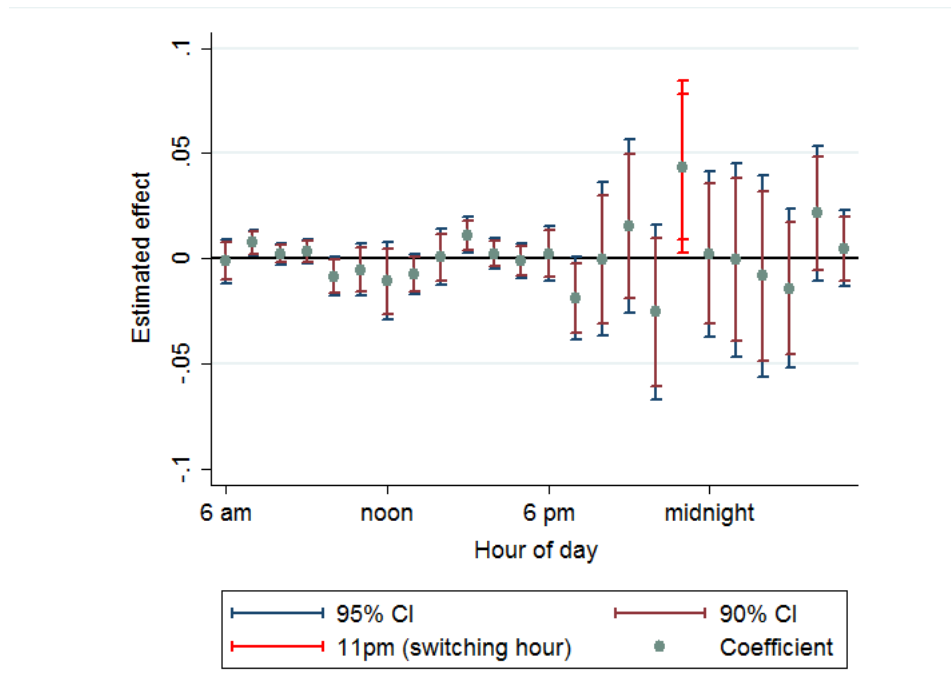

Notes: The figure plots treatment variable coefficients and their 90% and 95% confidence intervals from a difference-in-difference regression of gunfire incidents during the specified hour of the day, on all control variables from Equation 1, and netting out gunfire during 11pm on weekends to control for seasonal trends. Standard errors are clustered by day of year. Data source: Authors' calculations using ShotSpotter data from the Washington, DC, police department. Sample: 11pm–12:59am on July 30 through October 4, for the years 2006–2012. Geographic areas covered: Police Districts 3, 5, 6, 7; gunfire incidents are aggregated to the hour and Police Service Area (PSA) levels.

Table 1: Summary Statistics

	N	Mean	SD	Min	Max
Gunshots in Washington, DC					
Daily DC SST-detected incidents	483	7.795	5.659	0	38
Daily DC SST-detected incidents, 11pm-midnight	483	0.969	1.442	0	10
Daily DC SST-detected incidents, midnight-1am	483	0.874	1.293	0	9
Gunshots at the PSA-level (geographic unit of analysis)					
Daily PSA SST-detected incidents	11799	0.319	0.813	0	11
Daily PSA SST-detected incidents, 11pm-midnight	11799	0.040	0.259	0	6
Daily PSA SST-detected incidents, midnight-1am	11799	0.036	0.230	0	5
Crime at the PSA-level (geographic unit of analysis)					
Daily PSA MPD reported crimes	4278	1.791	1.552	0	15
Daily PSA MPD reported crimes, 11pm-midnight	4278	0.097	0.324	0	3
Daily PSA MPD reported homicides	4278	0.006	0.079	0	1
Daily PSA MPD reported homicides, 11pm-midnight	4278	0.001	0.026	0	1
Daily PSA MPD reported gun-involved crimes	4278	0.142	0.390	0	3
Daily PSA MPD reported gun-involved crimes, 11pm-midnight	4278	0.011	0.109	0	2
Daily PSA MPD reported violent crimes	4278	0.448	0.696	0	4
Daily PSA MPD reported violent crimes, 11pm-midnight	4278	0.034	0.188	0	2
Daily PSA 911 calls	4278	17.975	7.666	1	52
Daily PSA 911 calls, 11pm-midnight	4278	0.937	1.104	0	8
Daily PSA 911 calls for police	4278	13.896	6.214	0	41
Daily PSA 911 calls for police, 11pm-midnight	4278	0.766	0.973	0	7
Daily PSA 911 calls reporting gunshot	4278	0.142	0.423	0	4
Daily PSA 911 calls reporting gunshot, 11pm-midnight	4278	0.012	0.116	0	2

Notes: Geographic areas covered: Police Districts 3, 5, 6, 7. Sample: 11pm–12:59am on July 30 through October 4. ShotSpotter data on gunshot incidents cover 2006-2012. Reported crime and 911 call data cover 2011-2012. Data source: Washington, DC, police department.

Table 2: Effect of the 11pm curfew on gunfire incidents

	Main specification (1)	Include July curfew change (2)	Quadratic time trend (3)	Cubic time trend (4)
SST-Detected Gunshot Incidents				
Early curfew * Weekday * 11pm hour	0.045** (0.020)	0.037 (0.034)	0.035 (0.021)	0.047 (0.031)
Observations	22914	40186	22914	22914
Late curfew mean	0.030	0.034	0.030	0.030

* $p < .10$, ** $p < .05$, *** $p < .01$.

Notes: Standard errors are clustered by day of year and are shown in parentheses. Results are from DDD regressions from Equation 1, controlling for a linear time trend, unless otherwise noted. Outcome measure is the number of gunshot incidents. Analysis uses data from Police Districts 3, 5, 6, and 7, and gunfire incidents are aggregated to the hour and Police Service Area (PSA) levels. Sample: 11pm–12:59am on July 30 through October 4 (or May 30 through October 2 when the July curfew change is included), for the years 2006–2012. All specifications include the following control variables: whether school is in session; year, day of week, and PSA fixed effects; precipitation; and temperature. ShotSpotter data source: Washington, DC, police department. Weather data source: NOAA.

Table 3: Effect of the 11pm curfew on other measures of gun violence

	ShotSpotter Incidents (1)	MPD Reported Crime				911 Calls for Service		
		All (2)	Homicides (3)	Gun-Involved (4)	Violent (5)	All (6)	For Police (7)	To Report Gunshots (8)
Early curfew * Weekday	0.0261 (0.0243)	-0.0271 (0.0445)	-0.0026 (0.0021)	-0.0128 (0.0168)	0.0197 (0.0233)	0.1081 (0.1784)	0.0709 (0.1629)	-0.0029 (0.0146)

Late curfew mean	0.017	0.100	0.000	0.012	0.04	0.885	0.721	0.013

* $p < .10$, ** $p < .05$, *** $p < .01$.

Notes: Standard errors, clustered by day of year, are shown in parentheses. Results are from difference-in-difference regressions of the curfew on various outcomes during the 11pm hour on weekdays (the treated hour), netting out changes in the outcomes during 11pm on weekends (the control hour). Analysis uses data from Police Districts 3, 5, 6, and 7, and all outcomes are aggregated to the hour and Police Service Area (PSA) levels. Sample: 11pm–12:59am on July 30 through October 4, for the years 2011–2012. All specifications include all control variables from Equation 1 and a linear time trend. Column 1 shows effects on ShotSpotter incidents; columns 2–5 show effects on reported crime; columns 6–8 show effects on 911 calls. ShotSpotter, reported crime, and 911 call data source: Washington, DC, police department. Weather data source: NOAA.

A Appendix: Additional tables and figures

Figure A.1: ShotSpotter incidents over the full year
Notes: Graph shows the daily mean number of gunfire incidents detected in Washington, DC, for the years 2006–2012. The large spikes at New Year's and July 4 suggest that the sensors detect both celebratory gunfire and firecrackers that sound like gunfire. Data source: ShotSpotter data from the Washington, DC, police department.

Figure A.2: ShotSpotter incidents around July 4th
Notes: Graph shows daily mean number of gunfire incidents detected around the July 1 curfew change, 2006–2012. Number of gunshots is capped at 65 to allow a close-up of trends during that period. Data source: ShotSpotter data from the Washington, DC, police department.

Figure A.3: Effect of the 11pm curfew during the 11pm hour on weekdays, relative to the 11pm hour on weekends

Notes: Points show differences in mean residuals, by day, from a specification estimating the effect of the control variables and a linear trend controlling for the day of year on the number of gunfire incidents during the 11pm hour on weekdays, netting out gunfire during the 11pm hour on weekends. This shows unexplained variation in the outcome variable when comparing 11pm on weekdays (treated hour) with 11pm on weekends (control hour). The weekday curfew changes from midnight to 11pm on September 1. Sample: 11pm–11:59pm on July 30 through October 4, for the years 2006–2012. Data source: Authors' calculations using ShotSpotter data from the Washington, DC, police department.

Figure A.4: Effect of the 11pm curfew during the 11pm hour on weekdays, relative to the midnight hour on weekdays
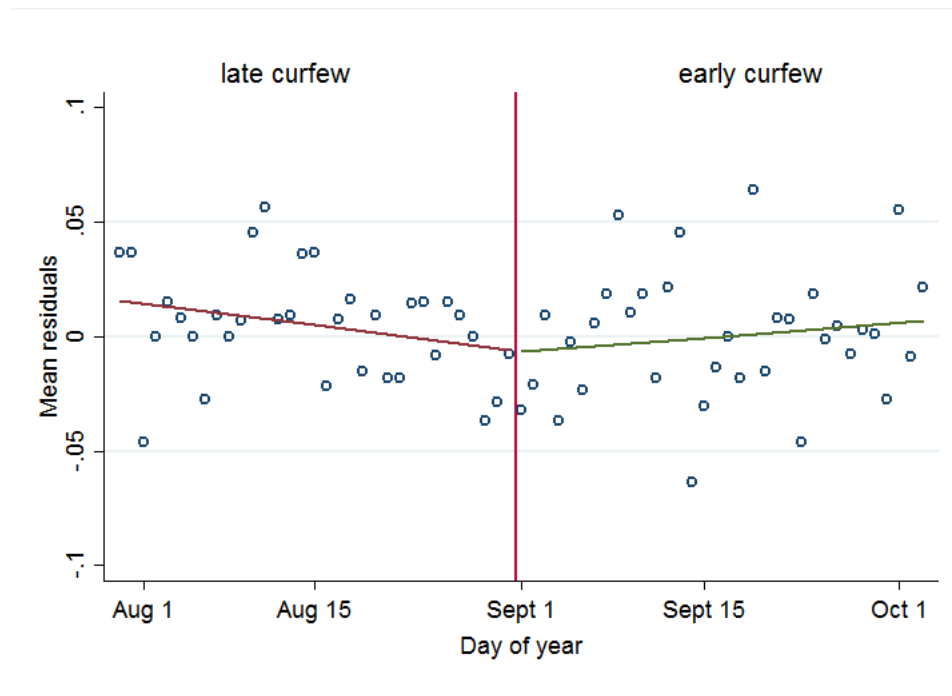

Notes: Points show differences in mean residuals, by day, from a specification estimating the effect of the control variables and a linear trend controlling for the day of year on the number of gunfire incidents during the 11pm hour on weekdays, netting out gunfire during the midnight hour on weekdays. This shows unexplained variation in the outcome variable when comparing 11pm on weekdays (treated hour) with midnight on weekdays (control hour). The weekday curfew changes from midnight to 11pm on September 1. Sample: 11pm–12:59am on weekdays, July 30 through October 4, for the years 2006–2012. Data source: Authors' calculations using ShotSpotter data from the Washington, DC, police department.

Figure A.5: Pre-period trends in residualized gunfire incidents for the treated hour vs. control hours
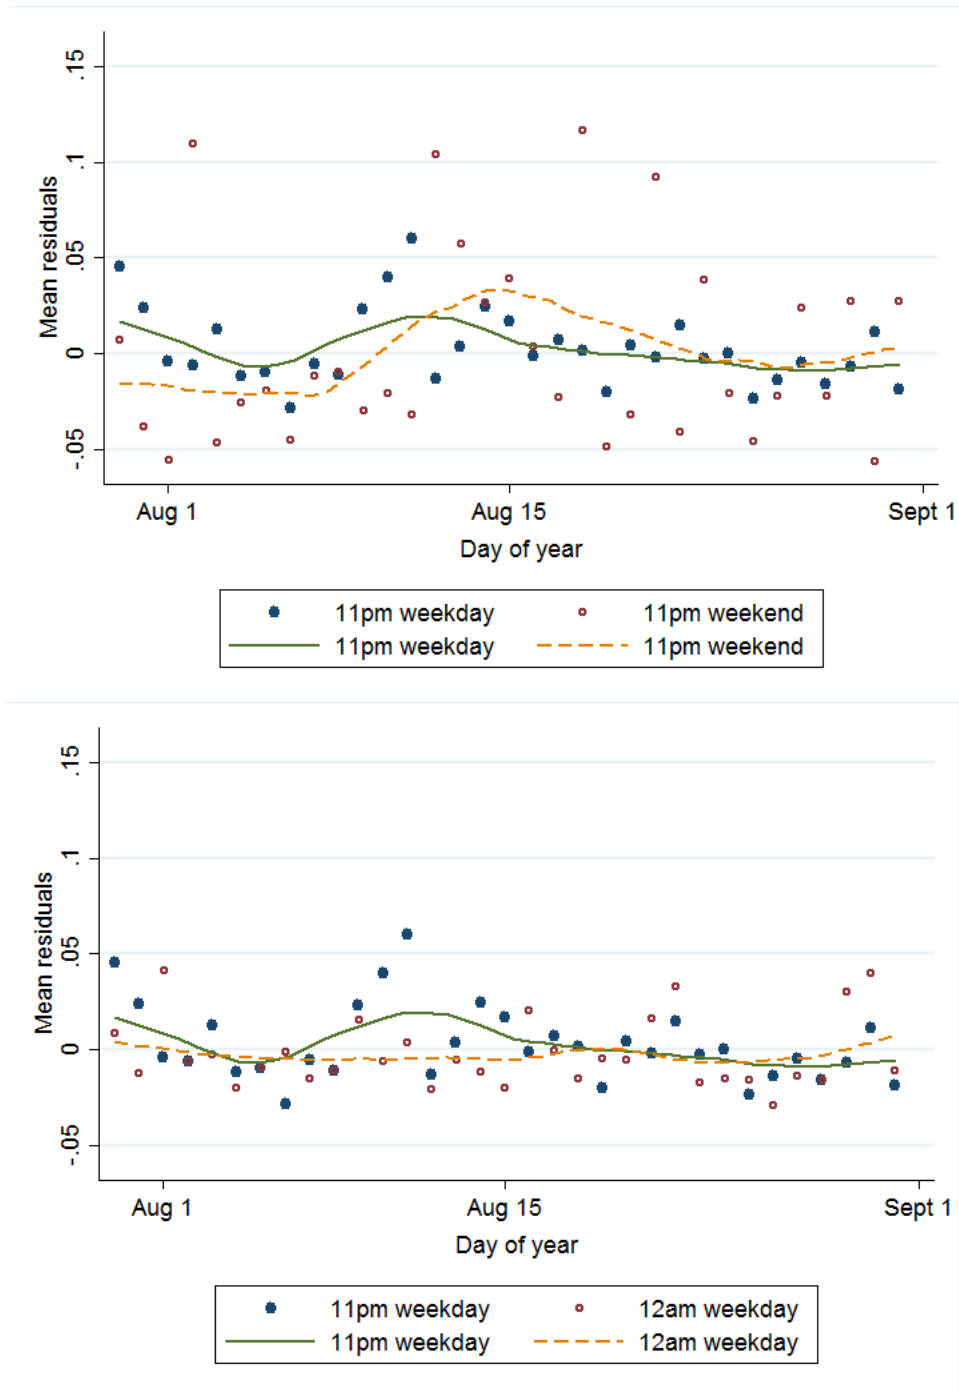

Notes: Graphs show mean residuals, by day, from regressions including all control variables from Equation 1 and a linear trend controlling for the day of year. The top graph compares residuals from the 11pm hour on weekdays with those from the 11pm hour on weekends. The bottom graph compares residuals from the 11pm hour on weekdays with those from the midnight hour on weekdays. Sample: 11pm–12:59am on July 30 through October 4, for the years 2006–2012. Data source: ShotSpotter data from the Washington, DC, police department.

Table A.1: Tests for diverging trends in ShotSpotter data

	11pm vs. Midnight (1)	Weekday vs. Weekend (2)
11pm hour * Time	-0.0007 (0.0004)	
Weekday * Time		-0.0010 (0.0008)
Observations	8038	5643

* $p < .10$, ** $p < .05$, *** $p < .01$.

Notes: Standard errors are clustered by day of year and are shown in parentheses. Coefficients are based on regressions of gunfire during the 11pm hour on weekdays, controlling for all control variables in Equation 1 and netting out gunfire during either the midnight hour on weekdays (column 1) or gunfire during the 11pm hour on weekends (column 2), and allowing the linear trend to differ across the two sets of hours. Estimates show differences in these linear trends before the curfew change on September 1, and speak to whether the treated hour and control hours exhibit parallel trends during the pre-period. Geographic areas covered: Police Districts 3, 5, 6, 7; gunfire incidents are aggregated to the hour and Police Service Area (PSA) levels. Sample: 11pm–12:59am on July 30 through October 4, for the years 2006–2012. ShotSpotter data source: Washington, DC, police department.

Notes: Standard errors are clustered by day of year and are shown in parentheses. Coefficients are based on regressions of each outcome, controlling for all control variables in Equation 1 and netting out the outcome measure during either the 11pm hour on weekends (panel 1) or during the midnight hour on weekdays (panel 2), and allowing the linear trend to differ across the two sets of hours. Estimates show differences in these linear trends before the curfew change on September 1, and speak to whether the treated hour and control hours exhibit parallel trends during the pre-period. Sample: 11pm–12:59am on July 30 through October 4, for the years 2011–2012. Geographic areas covered: Police Districts 3, 5, 6, 7; outcome measures are aggregated to the hour and Police Service Area (PSA) levels. ShotSpotter, reported crime and 911 call data source: Washington, DC, police department.
